Colorectal cancer is a malignant disease with high morbidity and mortality. Ki-67 is a marker of cell proliferation associated with a low survival in colorectal cancer patients. Its expression is increased in patients with Dukes C or D colorectal cancer versus those in stage A or B. The purpose of the study is to evaluate the immunohistochemical expression of the Ki-67 marker in colorectal adenocarcinomas. The study was performed on a group of 28 patients diagnosed with rectal cancer. We made the histopathological and immunohistochemical evaluation of patients in the study group. The evaluation was performed on the sections stained with hematoxylin-eosin, and for mucinous forms, on sections stained with alcian blue. The topography of the Ki-67 reaction is strictly nuclear, evident in areas with intense proliferative activity. In cases with a strong positive response to Ki-67, the prognosis is worse, with invasion of the perirectal tissues and metastases. The lack of Ki-67 expression in nearby neoplastic tissues suggests that cancerous tissue proliferates in a pathway that it is not correlated with adjacent tissues. The Ki-67 could be useful in the prognosis of patients with colorectal cancer.

**Keywords:** colorectal cancer, Ki-67 immunohistochemical expression, prognosis
The nuclear accumulation of the Ki-67 protein was assessed semi-quantitatively: negative (-) which means lack of coloration or presence in less than half of the cells and positive (+) which means the presence of nuclear staining in over 50% of tumor cells. In turn, the positive response was assessed low positive, moderately positive and strongly positive (+, ++ and +++).

Results and discussions

Most of the studied cases were moderate and low differentiated colorectal adenocarcinomas (G2 and G3). Approximately 60% were in advanced stages (T3), with perirectal adipose tissue invasion.

In G2 adenocarcinomas (fig.1), tumor cells delineate glandular, irregular cavities sometimes with papillary excrescences of different shapes and sizes. The nuclei are large, elongated, hypercromatic, placed on 3-4 layers that occupy the entire thickness of the epithelium. There are areas of ulceration and infection with the presence of stromal inflammatory infiltrates.

In G3 adenocarcinomas, tumor cells are usually small with hyperchromic nuclei. The stromal volume is increased, there are frequent ulceration areas, the stromal inflammatory infiltrate being abundant (fig. 2).

Of all the cases of studied colorectal tumors, we considered mucinous carcinomas the cases where the mucinous component represented more than 30% (fig. 3).

Immunohistochemical exam in sections stained for Ki-67 has shown that the topography of reaction is strictly nuclear (fig. 4-6), but we could not accurately identify the nuclear localization depending on the division stage. In the tumor there are Ki-67 poor stained areas, probably due to the completion of phase (interphase) and degradation of nuclear staining.

The lack of expression of studied markers in neighboring non-tumor tissues, including Ki-67, suggests that cancerous tissue proliferates in a pathway that is not correlated with adjacent tissues.

In cases with a strong positive response to Ki-67 (+++), prognosis is worse, with invasion of the perirectal tissues, regional lymph nodes and metastases. In these situations there is a direct correlation between the expression and accumulation of the Ki-67 protein and the local, regional or distant extension.

We have not noticed any correlation between the intensity of the reaction and the age and gender of the patient or the exact location of the primitive tumor.

Ki-67, marker of cell proliferation is associated with a low prognosis in colorectal cancer patients. Its expression is increased in patients with Dukes C or D colorectal cancer versus those in stage A or B. The Ki-67 along with other clinical-pathologic markers could be useful in the prognosis of patients with colorectal cancer.

The growth rate of cancer cells depends on their proliferative activity and cell death rate. Researchers [15] evaluated the expressions of Ki-67, PCNA, MCM in 55 patients diagnosed with colorectal carcinomas and showed that the expressions of the three antibodies are directly correlated with the presence of metastatic lymph nodes but are independent of the age and location of the tumor. It can be concluded that their positive expressions in the mass of the main tumor are directly proportional to pathological stage and histological differentiation gradient.

Neoplastic growth is characterized by uncontrolled proliferation well above the cell death rate, as well as loss...
of cell differentiation. For this reason a neoplasm means a cell growth disorder evidenced by excessive cellular proliferation. Determination of this proliferation can be used in the positive diagnosis and prognosis of neoplastic lesions, as a prognostic marker [17,18] as well as a screening test in individuals with high risk.

The value of the Ki-67 expression has a normal limit in the free mucosa, being somewhat higher in adenomas, and the maxima in adenocarcinomas [19-21]. Researchers found a correlation between the histological degree of malignancy and the depth of tumor infiltration in the wall [22]. Determination of Ki-67 may subdivide a group of patients with similar clinical symptoms into diagnostic and prognostic subgroups.

Since 1988, it has been shown that the immunohistochemical determination of Ki-67 may have clinical application in the selection of patients with colorectal cancer who may benefit from radiotherapy and/or chemotherapy, particularly those with unresectable or locally recurrent tumors [23-28].

Research on colorectal carcinomas using immunohistochemical techniques with Ki-67 protein is simple and relatively easy to apply. The results are reproducible using the MIB 1 antibody with which excellent stains can be obtained, even on the classically fixed paraffin blocks [29-35]. Ki-67 expression is high in non-mucosal adenocarcinomas, highly or moderate differentiated, and is low in those that are low differentiated with mucin secretion. This last type of tumor corresponds to an advanced Dukes stage. Thus, there is a close association between the histological grade, type and stage of the tumor.

Conclusions

Increased expression of the Ki-67 marker is generally associated with a low prognosis of survival, especially in undifferentiated or low differentiated cases of colorectal carcinomas. The Ki-67 along with other clinical-pathologic markers could be useful in the prognosis of patients with colorectal cancer.
